

Graph coloring based Optimal Wireless Energy Redistribution in WSNs

Author1, Author2, Author3

Abstract—Wireless energy redistribution based on wireless power transfer technology is a core building block for supporting perpetual wireless sensor networks (WSNs) charged with moving or fixed wireless chargers, and it is especially important for prolong the network normal operation time when WCs could not to charge the network timely. In this paper, we investigated the wireless power transfer based energy redistribution (WPTERD) problem in WSNs, which is to redistribute the energy among network nodes so that all nodes' expected energy amount are satisfied when possible, meanwhile guaranteeing that the energy lost in this process is minimized, and the time length of the redistribution process is minimized. By analyzing some properties of the WPTERD problem, we propose a two-step approach which solves two embedded sub-problems named WPTERD-Egy and WPTERD-Time in turn. The two sub-problems focus exclusively on the optimization in energy and time, respectively. In the first step, we re-formulate the WPTERD-Egy problem as a linear programming (LP) problem, which returns the optimal energy transmission time lengths of the nodes leading to minimum energy lost. The core work of the WPTERD-Time problem in the second step is to find a minimum makespan schedule of energy transmission time slices. We prove that the WPTERD-Time problem is NP-hard, and propose graph coloring based Energy Transmission Scheduling (GC-ETS) algorithm to find an approximate energy transmission schedule solution to the WPTERD-Time problem. We also obtain some approximation ratios of GC-ETS for 2D WSNs and 3D WSNs, respectively. Combining the two steps, we propose GC-based Wireless Energy ReDistribution Scheduling GC-WERDS algorithm to solve the WPTERD problem completely. Numerical simulations illustrate the effectiveness and efficiency of GC-WERDS, which return schedules with minimum energy lost and approximately minimum makespan. By exploiting parallel opportunities of energy transmissions, GC-WERDS reduces makespan by about more than 60% when compared with a schedule without exploiting the parallel energy transmission opportunities, at the expense of 10% more energy transmission switches.

Index Terms—wireless energy redistribution problem, wireless power transfer, task scheduling problem, wireless charging, graph coloring problem.

I. INTRODUCTION

RECENT breakthroughs in the areas of Wireless Power Transfer(WPT) technology [1], [2] and rechargeable batteries [3] open up a new dimension to prolonging the lifetime of wireless sensor networks (WSNs). WPT is the transmission of electric energy from a power source to a receiver without a conductor. With recent advances in WPT, it is possible to charge sensor nodes in a relative long distance ($> 10\text{m}$ away)[4]. It has been validated that sensor node could harvest radio power of 6mW from a wireless charger with 4W transmission power over a distance of 12 meters. The

received radio power is 20mW and the transition efficiency is 30 percent [5].

WPT will have a profound impact on the design of WSNs attributed to its obvious advantages, and hence many research efforts have been devoted to exploiting WPT to enhance WSNs [6]-[13]. Some works focus on the application of using dedicated fixed or mobile nodes called wireless chargers (WCs) for powering the normal nodes in WSNs using WPT. Due to the limited number of WCs, some nodes may could not obtain power from the WCs directly. This is true even if there are mobile WCs, because that there may be some restrictions on their movement, or the WCs may be fail temporally. Hence, WPT based Energy ReDistribution (WPTERD) is a core building block for supporting perpetual WSNs.

In recent years some research efforts have been devoted on WPTERD-like application, where the nodes exchange energy in peer-to-peer mode when coming into vicinity of each other during moving, so as to make the nodes' remained energy become more balanced. However, the intrinsic broadcasting feature of energy transmitting signals, which means multiple nodes may harvest energy simultaneously from the signal transmitted by a single node, is not exploited, and hence leads to lower energy efficiency.

In this paper, we focus on the WPTERD problem for WSNs: given a WSN with nodes all equipped with wireless power transceivers and limited energy storages containing some known energy, the task is to redistribute the energy in the network among all nodes through WPT, assuring that the energies of the nodes after the redistribution all do not below their energy expectations, meanwhile the energy loss is minimized and the time length (called makespan) of the energy redistribution process is minimized. We solve the WPTERD problem in two steps. In the first step, basing on a proved property resulted from the widely adopted *energy harvesting additive assumption*, the WPTERD problem with only the minimum energy loss objective (named as WPTERD-Egy) is formalized as a Linear Programming (LP) problem, and can thus be solved to obtain the time lengths of the nodes' energy transmission operations. With the results in the first step, the remanent of the WPTERD problem becomes a task scheduling problem of the nodes' energy transmission operation time intervals, denoted as WPTERD-Time. Proving that the WPTERD-Time is NP-hard, we propose a Graph Coloring (GC) based Energy Transmission Scheduling (GC-ETS) algorithm, which makes up the second step. The approximation ratios of GC-ETS for 2D WSNs and 3D WSNs are proved, respectively. By solving the WPTERD-Egy with mature LP solvers first, and then using the GC-ETS algorithm to obtain an energy transmission schedule, our algorithm GC-WERDS returns an approximate

optimal schedule with minimum energy loss, quasi-minimum makespan, and thus solve the WPTERD problem completely. Numerical simulations illustrate the effectiveness and efficiency of GC-WERDS, which return schedules with minimum energy loss and approximately minimum makespan. By exploiting parallel opportunities of energy transmissions, GC-WERDS reduces makespan by about 30% when compared with a schedule without using the parallel opportunities.

Our main contributions in this paper are as follows:

- We solve the WPTERD problem completely by dividing it into two sub-problems WPTERD-Egy and WPTERD-Time, and solve the WPTERD problem in two steps which solve the WPTERD-Egy problem and the WPTERD-Time problem, respectively. This approach exploits the broadcast nature of wireless signals well, and implicitly realizes the multi-hop energy transmission easily.
- For the WPTERD-Egy problem, we prove that its optimal solutions must be disjoint solutions, where energy transmission time intervals of neighboring nodes should not overlap in time line.
- For the WPTERD-time problem, we prove that it is NP-hard, and propose the GC-ETS algorithm to solve it and thus solve the WPTERD problem approximately. Additionally, we prove that, if the approximation ratios of GC-ETS for 2D WSNs and 3D WSNs are 6 and 24, respectively. When restricted to cases where all nodes the same energy transmission radius, then the approximation ratios of GC-ETS for 2D WSNs and 3D WSNs are 3 and 12, respectively.

The rest of the paper is organized as follows. Related work is discussed in Section II. The models of the problem are described in Section III. Analysis results and the method to solve the WPTERD-Egy problem are described in Section IV. In Section V, the NP-hard property of the WPTERD-Time problem is proved. In Section VI, we provide the GC-ETS algorithm, and prove its approximation ratios. The whole algorithm GC-WERDS for solving the WPTERD problem by solving the WPTERD-Egy problem and the WPTERD-Time problem in-turn are provided in Section VII. Simulation results are provided and discussed in Section VIII. Finally, we conclude this work in Section IX.

II. RELATED WORK

Existing works using WPT most related to our work fall into two topics: (1) charging WSNs with fixed WCs; (2) energy redistribution among nodes in WSNs.

A. Charging WSNs with fixed WCs

In [6], focusing on a WSN containing a fixed wireless charger (WC) as the only energy source for the network, the problem of distributing the energy injected from the access point among all nodes through multi-hop WPT was investigated. In the approach there, the energy transfers in the network are modeled and formulated as multi-hop energy flows, and algorithms were proposed.

WSNs with multiple WCs and multi-hop power transfer technique were focused in [7]. In this work, considering the energy demand of the nodes, the energy loss that occurs during an energy transmission and the energy capacity limits of the WCs, the problem of determining the minimum number of WCs needed for perpetual operation of the WSN was investigated. The approach there solves the problem in two steps. In the first step, for each possible location of the WCs (WCs are assumed to be located at network nodes), a shortest path tree rooted at this location that covers all the nodes is constructed using the Dijkstra's algorithm. Then in the second step, the problem is transformed to a Mixed Integer Linear Programming (MILP) problem making use of the trees constructed in the first step, and the MILP is solved using mature optimization software packages.

The works in [4], [8] also devoted to WSNs with multiple WCs, but with an emphasis on exploiting the possibility of multiple WCs charging a single node simultaneously. A more complicated energy harvesting model considering the nonlinear superposition charging effect of simultaneously arrived energy signals was proposed there. Basing on this model, the joint charging utilities for all possible set of the WCs are pre-calculated and then be used to solve the concurrent charging scheduling problem (CCSP), whose objective is to find a schedule for the WCs so as to minimize the time spent on providing each sensor node with at least E energy more. The authors showed that CCSP is NP-hard, and proposed a greedy algorithm based on sub-modular set cover problem as well as a genetic algorithm for the CCSP. However, only one-hop WPT is considered in these works.

Multi-hop wireless power transmission is considerably different from multi-hop data transmission. For data, different transmissions are usually different since they convey different data. For energy, however, energy from any source are equivalent, we need not explicitly construct paths and restrict energy flows along a certain graph. In some sense, opportunistic routing in the wireless network routing realm is more suitable for energy transmission. Hence, finding other mechanisms of multi-hop WPT for the wireless charging of WSNs is of importance.

B. Energy Redistribution Among Nodes

Some series of recent works [9], [10], [11], [12], [13] focus on a problem similar to our WPTERD problem for mobile social and sensor networks, which consist of human-carried mobile devices. In these works, energy redistribution is realized using peer-to-peer energy exchange, which happens only when nodes coming into vicinity of each other because of the moving of the person carrying the node.

Firstly in [9], the authors investigated the problem of selecting a subset of nodes to charge the rest nodes in the network such that all nodes can continue normal operations without battery depletion. In [10], the authors investigated the problem of efficiently reaching an energy balance among network nodes distributively though peer-to-peer energy exchange. The problem was investigated for two different assumptions: lossless power exchange and lossy power exchange. Three energy

exchange protocols were designed, analyzed and evaluated there. Then the problem was extended to the weighted version in [11]. The uniform balance version and the weighted balance version of the peer-to-peer energy redistribution problem among star-backbone nodes in WSNs were investigated in [12] and [13], respectively.

In these works, energy exchange only happens when two nodes coming into vicinity of each other. As a consequence, their analyses and algorithms do not exploit the intrinsic broadcasting nature of wireless signals as well as the capability of WPT's transferring energy over a distance. Ignoring the possibility of multiple nodes simultaneously harvesting energy from a single node's energy transmitting signals inevitably leads to energy in-efficiency.

III. SYSTEM MODEL

A. Problem Model

We consider a WSN consisting of n static nodes $U = \{u_1, u_2, \dots, u_n\}$, where node u_i is positioned at $(x(i), y(i), z(i))$. An example network is shown in Fig.1. The nodes are equipped with energy storage of capacity limits described as function $e_U: \mathcal{N}(n) \rightarrow \mathcal{R}^+$, i.e., the capacity limit of node u_i is $e_U(i)$. We assume node u_i 's energy should always do not below its lower limit $e_L(i)$. Besides the traditional wireless transmitter/receivers (transceivers) for data communication, these nodes are all equipped with wireless energy transceivers dedicated for transmitting/harvesting energy. Suppose node u_i currently has energy $e_B(i)$, $i \in \mathcal{N}(n)$. We are required to redistribute the energy among the nodes in by using WPT, with the objective that node u_i 's energy $e_F(i)$ at the finish of the redistribution process should not below its expectation $e_E(i)$, $i \in \mathcal{N}(n)$. We express the objective as $e_F \succeq e_E$ for short. We assume that the energy expectation of node u_i has a lower limit $e_{E,L}(i)$. We also assume $e_L \prec e_{E,L} \preceq e_E \prec e_U$ and $e_L \prec e_E \prec e_U$ always hold. For convenient, function e_U is sometimes called as list or vector when causing no confusion, which also applies to other similar symbols. For easy reference, we list the symbols and their meanings in Table I.

Fig. 1. An example network with WPT based energy redistribution.

Assume node u_i always transmits energy with a constant power $p(i)$, $i \in \mathcal{N}(n)$. When node u_i is transmitting energy, the energy power harvested by node u_j from u_i 's signal is expressed as $p_H(j) = c(j, i) * p(i)$, where the energy harvesting

TABLE I
NOTATIONS AND MEANINGS.

Notation	Meaning
$\mathcal{N}(n)$	The set of positive integers $\{1, 2, \dots, n\}$;
\mathcal{R}^+	The set of positive real value in range $[0, +\infty]$;
p, \mathbf{P}	The function/list/vector of the node's constant energy transmitting power, node u_i 's energy transmit power is $p(i)$;
$[\cdot]^T$	Transpose operation of the input matrix or vector;
\mathbf{C}	The matrix of the energy harvesting coefficients $[c(i, j)]_{i, j \in \mathcal{N}(n)}$, $c(i, j)$ is the energy harvesting coefficient for node u_i receives energy from u_j ;
\mathbf{t}	The vector of the nodes' energy transmitting time lengths $\mathbf{t} \triangleq [t(1), t(2), \dots, t(n)]^T$;
e_B, \mathbf{e}_B	The function/list/vector of the nodes' energy at the beginning time where it is $e_B(i)$ for u_i . $\mathbf{e}_B \triangleq [e_B(1), e_B(2), \dots, e_B(n)]^T$;
e_F, \mathbf{e}_F	The function/list/vector of the nodes' final energy after the energy redistribution process finishes where it is $e_F(i)$ for u_i . $\mathbf{e}_F \triangleq [e_F(1), e_F(2), \dots, e_F(n)]^T$;
e_U, \mathbf{e}_U	The function/list/vector of the nodes' energy upper limits where it is $e_U(i)$ for u_i . $\mathbf{e}_U \triangleq [e_U(1), e_U(2), \dots, e_U(n)]^T$;
e_L, \mathbf{e}_L	The function/list/vector of the nodes' energy lower limits where it is $e_L(i)$ for u_i . $\mathbf{e}_L \triangleq [e_L(1), e_L(2), \dots, e_L(n)]^T$;
e_E, \mathbf{e}_E	The function/list/vector of the nodes' energy expectations where it is $e_E(i)$ for u_i . $\mathbf{e}_E \triangleq [e_E(1), e_E(2), \dots, e_E(n)]^T$;
$e_{E,L}, \mathbf{e}_{E,L}$	The function/list/vector of the nodes' lower limits of energy expectations where it is $e_{E,L}(i)$ for u_i . $\mathbf{e}_{E,L} \triangleq [e_{E,L}(1), e_{E,L}(2), \dots, e_{E,L}(n)]^T$;
$\mathbf{1}$ or $\mathbf{0}$	Proper size column vectors with elements all one or all zero, respectively;
$\mathbf{1}_{condi}$	The indication function of condition <i>condi</i> , which has value 1 when <i>condi</i> is true, and 0 otherwise;
$\mathcal{N}(i)$	The set of neighbors of node u_i , two nodes u_i and u_j are neighbors of each other if $c(i, j) + c(j, i) > 0$;
$N_{H,y}(v)$	The set of node v 's neighbors in graph H together with/without node v itself;
$w(S)$	The accumulated weight of the nodes in S ;
$\varpi(G)$	$\varpi(G) \triangleq \max_{H \subseteq G} (\min_{v \in H} w(N_{H,y}(v)))$;

coefficient $c(i, j)$ abstracts the effects of many factors such as the distance between the nodes, the environment, the hardware restriction, etc. Energy harvesting coefficients are always non-negative. If $c(i, j) + c(j, i) > 0$, then we say that u_i and u_j are neighbors. Furthermore, because of the energy conservation principle in practice, energy loss is inevitable during the wireless energy redistribution process, hence we assume $\sum_{j \neq i, j \in \mathcal{N}(n)} c(j, i) < 1$, $i \in \mathcal{N}(n)$. For completeness, we let $c(i, i) = -1$, $i \in \mathcal{N}(n)$. We collect all energy harvesting coefficients into a matrix $\mathbf{C} = [c(i, j)]_{i, j \in \mathcal{N}(n)}$.

We assume that the energy harvesting coefficients of the nodes are constant. Moreover, multiple simultaneous energy transmissions encountered at a node are assumed to be additive, which is the *energy harvesting additive assumption* widely adopted in the literature[15], [16], [17]. In other words, if a set of nodes $\{u_j | j \in U_s\}$ transmit energy with power $\{p_j | j \in U_s\}$ to another node u_j simultaneously, then the energy power harvested by u_j is $p_H(j) = \sum_{k \in U_s} c(j, k) * p(k)$. Harvested energy should be stored in the energy storage for later use. Excessive energy harvested by node u_i is lost when the energy storage is full of energy.

To fulfil the objective of the WPTERD problem, we have to find an energy transmission schedule $s_c \triangleq \{s(1), s(2), \dots\}$ where $s(i) \triangleq (u_s(i), t_b(i), t_e(i))$ represents a schedule item, which means to let node $u_s(i) \in U$ transmit energy in time

slice $[t_b(i), t_e(i)]$. Given a schedule, if each node u_i can only exist in at most one schedule item, then this schedule is *non-preemptive*, otherwise it is *preemptive*. We mainly consider preemptive schedules in this paper. An energy transmission schedule is valid if we have $e_F \geq e_E$ after performing the energy redistribution process according to the schedule. A valid schedule with *maximum accumulated final energy* $E_C(s_c) = \sum_{i=1}^n e_F(i)$ is called an *optimal schedule*. For the WPTERD problem, it is obvious that *maximizing accumulated final energy* is equivalent to *minimizing the energy loss*, hence we use the two phases alternatively for convenience. We denote $t_E(s_c) \triangleq \max_{i:s(i) \in s_c} t_e(i)$ and call it the *schedule length* of s_c . Short schedules are preferred. In the literature of job/task scheduling, it has the *makespan* [14]. We will use the two concepts alternatively for convenience.

Formally, we state our WPTERD problem as follows. Given a set of static nodes U in a given space with energy harvesting coefficient matrix $C = \{c(i, j)\}$, energy storage capacity limit list e_U (vector), energy storage lower limit list e_L , energy transmitting power list p , beginning energy list e_B , expected energy list e_E , the task is to find a valid energy transmission schedule s_c with maximum accumulated final energy $E_C(s_c)$ and further with minimum makespan $t_E(s_c)$.

B. Energy Harvesting Model

The energy harvesting model determines the energy harvesting coefficients. Although any energy harvesting model can be applied, we adopt a model where energy harvesting coefficient is determined using Eq.(1). In (1), α, β, γ are known constants determined by hardware parameters of the energy transceivers as well as the surrounding environment, and D is the farthest distance that the energy transmitting signal can reach when the energy transmitting power $p=1$. $\gamma \in [2, 6]$ represents the channel fading effect and it is 4 in free space.

$$c(d) = \begin{cases} \frac{\alpha}{(\beta+d)^\gamma}, & d \leq D * p^{1/\gamma}; \\ 0, & d > D * p^{1/\gamma}, \end{cases} \quad (1)$$

Our energy harvesting model extends the model in [16] in two aspects: (1) adds one new parameter γ , which consists with the popular wireless signal transmission model; (2) makes the energy coverage radius depends on the energy transmitting power, which is more practical. Furthermore, the model is not restricted to 2D or 1D space, in fact 3D space also applies.

Comment: *the analyses and proposed algorithm in later sections do not depend on certain energy harvesting model. The model in (1) is only used in the simulation experiments in Section VIII.*

IV. SOLVE THE WPTER-EGY PROBLEM

By analyzing some properties of the WPTERD problem, we propose a two-step approach which solves two embedded sub-problems named WPTERD-Egy and WPTERD-Time in turn. The two sub-problems focus only on the optimization in energy and time, respectively. In the first step, by formulating the WPTERD-Egy problem based on interesting property of the problem in a linear programming (LP) form, we obtain the optimal energy transmitting time lengths of the nodes

leading to minimum energy loss. With the results in the first step, the remanent work of the WPTERD problem becomes the WPTERD-Time problem, which is to find a minimum makespan schedule of energy transmission operations not violating the nodes' energy limits. We call a continuous time interval of a node's energy transmission operation as an *energy transmission time slice*, hence the WPTERD-Time problem is to schedule the energy transmission time slices. We use *time slice* to represent *energy transmission time slice* by default for simplicity.

We will provide our analysis and treatment on the WPTERD-Egy problem in this section. The treatments on the WPTERD-Time problem are provided in later sections.

A. Problem Formulation of the WPTERD-Egy Problem

Let S_C be the space of all valid energy transmission schedules. Given a schedule $s_c \in S_C$, we can sort all items of $t_b(i)$ and $t_e(i)$ into a list $T_s(s_c) = [t_1, t_2, \dots, t_L]$ in ascending order. Here the list is assumed to have length L . The time points in $T_s(s_c)$ divide the time interval $[0, t_L]$ into time slots $\{ts(1), ts(2), \dots, ts(n)\}$, where $ts(i)$ represents the slot $(t_{i-1}, t_i]$. For each slot $ts(i)$, we can obtain the set of nodes $U_T(i)$ who are scheduled to transmit energy in slot $ts(i)$, and meanwhile all the others $U_H(i) = U - U_T(i)$ harvest energy.

During the energy redistribution process, node u_i 's energy changes along time $t \in [0, t_L]$. Denoting the function of u_i 's energy on time t and energy transmission schedule s_c as $e_i(s_c, t)$, then it can be expressed recursively as Eq.(2).

The WPTERD-Egy problem can then be formulated as Eq.(3).

$$(\mathbf{P1}) \quad \begin{aligned} & \max_{s_c \in S_C} \quad \sum_{u_i \in U} e_i(s_c, t_E(s_c)) \\ & \text{s.t.} \quad e_i(s_c, t_E(s_c)) \geq e_E(i), \quad i \in \mathcal{N}(n); \\ & \quad e_i(s_c, t_E(s_c)) \leq e_U(i), \quad i \in \mathcal{N}(n); \\ & \quad e_i(s_c, t) \leq e_U(i), \quad i \in \mathcal{N}(n), t \in [0, t_E(s_c)]; \\ & \quad e_i(s_c, t) \geq e_L(i), \quad i \in \mathcal{N}(n), t \in [0, t_E(s_c)]; \end{aligned} \quad (3)$$

The WPTERD-Egy problem has several challenges: (1) it is nonlinear due to the lower and upper limits of nodes energy; (2) the solution space S_C is infinitely larger because that the variables t_i can take any real values from the continuous time interval $[0, t_E(s_c)]$, and $t_E(s_c)$ also requires to be determined.

Further inspections show that, what significantly affect the nodes' final energy are their energy transmission time lengths, not the beginning and ending time of the time slots. Hence, to overcome the challenges, we will focus only on determining the optimal energy transmission time lengths leading to minimum energy loss in the WPTERD-Egy problem.

The restrictions on each node's energy of not violating the lower and upper energy limits during the energy redistribution process are postponed to the WPTERD-Time problem, and hence are ignored in the WPTERD-Egy problem.

B. Analyses on the WPTERD-Egy Problem

During the energy redistribution process, excessive energy harvested of a node is lost when its energy storage is full

$$e_i(s_c, t) = \begin{cases} e_B(i), & t=0; \\ \min \left\{ e_U(i), \max \left[0, e_i(s_c, t_{j-1}) + \left(\mathbf{1}_{i \in U_H(j)} \sum_{k \in U_T(j)} p(k)c(k, i) - \mathbf{1}_{i \in U_T(j)} p(i) \right) (t - t_{j-1}) \right] \right\}, & t \in (t_{j-1}, t_j], \\ & j \in \mathcal{N}(L); \end{cases} \quad (2)$$

of energy. Given an energy transmission schedule, if some harvested energy are lost at some nodes, we say that *this schedule has energy upper limit violations*.

About energy transmission schedules with energy upper limit violations, we have the following lemma.

Lemma 1: For any valid energy transmission schedule with some energy upper limit violations, there must be some valid energy transmission schedules with more accumulated final energy.

Proof: Without loss of generality, we denote the given schedule with violations as s_0 , and assume the violation is happened at node $v_0 \in U$. Then we analyze the situation by dividing into the following two cases:

- **case1:** $\exists v_i \in \mathcal{N}(v_0)$ with $e_F(v_i) < e_U(v_i)$. For the purpose to generate a better schedule with no violation, we assume each node is equipped with an auxiliary energy storage which can store the lost energy because of the violation on its energy upper limits. Then, after s_0 finishes, we can let node v_0 try to use-up the energy in its auxiliary storage (assume the amount of the energy is e_{v0}) by an additional energy transmission time slice of length $e_{v0}/p(v_0)$. The node v_i will harvest energy $c(v_i, v_0) * p(v_0) * e_{v0}/p(v_0) = c(v_i, v_0) * e_{v0}$ from this energy transmission, and its new final energy will become $e'_F(v_i) = \max(e_F(v_i) + c(v_i, v_0) * e_{v0}, e_U(v_i))$. With the given condition that $e_F(v_i) < e_U(v_i)$, we have $e'_F(v_i) > e_F(v_i)$. Meanwhile, all other nodes' new final energy will at least not decrease. Thus, total accumulated final energy after v_0 's last energy transmission will be greater than that of s_0 . Furthermore, we can obtain a new schedule s_1 by scheduling v_0 's last energy transmission to earlier times such that the violation at v_0 does not happen, which is true since that we can extend the makespan of the whole schedule when necessary. The new schedule s_1 may still have violations at other nodes, but the violation at node v_0 is avoided.
- **case2:** $\forall v_i \in \mathcal{N}(v_0)$ we have $e_F(v_i) = e_U(v_i)$. In this case, there must be a node v_1 with $e_F(v_1) < e_U(v_1)$ in the network such that there is a path $\{v_0 = a_1, a_2, \dots, a_k = v_1\}$ connects v_0 and v_1 , as illustrated in Fig.2. As in the previous case, we also assume each node is equipped with an auxiliary energy storage. Then, after s_0 finishes, we can let node $a_i, i \in \mathcal{N}(k-1)$, to make additional energy transmissions in turn so as to use-up the excessive energy e_{v0} at v_0 , meanwhile make $e'_F(a_i) = e_F(a_i) = e_U(v_i)$, $i \in \mathcal{N}(k-1)$, $e'_F(a_k) > e_F(a_k)$. The time lengths of the additional transmissions $t(a_i), i \in \mathcal{N}(k-1)$, can be obtained by solving the following Eq.(4). Furthermore, we can obtain a new schedule s_1 by scheduling these additional energy transmissions to earlier times such that violations

at $a_i, i \in \mathcal{N}(k-1)$, do not happen.

Combining above cases, the lemma follows. \blacksquare

Fig. 2. The path connects v_0 and v_1 with $e_F(v_1) < e_U(v_1)$.

Based on Lemma 1, we have the following theorem further.

Theorem 1: Optimal energy transmission schedules with maximum accumulated final energy (i.e., minimum energy loss) must have no upper limit violations.

Proof: It can be proved easily by contradiction. If there is an optimal schedule s_1 with violations, then by applying Lemma 1 we can obtain a new better schedule s_2 , which contradicts with the assumption that s_1 is optimal. \blacksquare

For any energy transmission schedule s_1 , if there is a set of neighboring nodes whose time slices in s_1 overlap (partly or completely), then we can obtain a new schedule s_2 by just moving the overlapped time slices apart meanwhile guaranteeing that they all do not overlap with all other nodes' time slices. This is absolutely possible since that we can always increase t_L when necessary. We call a schedule where neighboring nodes' time slices do not overlap as a *disjoint schedule*, otherwise an *overlap schedule*.

For the relative priority of the two schedules s_1 and s_2 in term of accumulated final energy E_C , we have the following lemma.

Lemma 2: For the two energy transmission schedules s_1 and s_2 obtained as above and assume they both have no energy upper limit violations, we have $E_C(s_2) > E_C(s_1)$.

Proof: Basing on the *energy harvesting additive assumption*, and according to Eq.(2), we analyze the following cases:

- **case1: the set of neighboring nodes whose time slices overlap only contains two nodes.**

Assume the two neighboring nodes as u_i and u_j . Replacing s_1 with s_2 will not affect the amount of energy harvested by any other node u_k , i.e., $e_k(s_1, t_E(s_1)) = e_k(s_2, t_E(s_2))$, $\forall k \in \mathcal{N}(n), k \neq i, j$. It is also easy to notice that, the energy harvested by u_i and u_j from all the other nodes are kept unchanged when replacing s_1 with s_2 .

Now we analyze the harvested energy of u_i from u_j in s_1 and s_2 , respectively. We assume the lengths of u_i and u_j 's energy transmitting time intervals in s_1 are respectively $t(i)$ and $t(j)$. Furthermore, assume that

$$\begin{bmatrix} -1*p(a_1) & c(a_1, a_2)*p(a_2) & \dots & 0 & 0 \\ c(a_2, a_1)*p(a_1) & -1*p(a_2) & \dots & 0 & 0 \\ 0 & c(a_3, a_2)*p(a_2) & \dots & 0 & 0 \\ 0 & 0 & \ddots & -1*p(a_{k-2}) & c(a_{k-2}, a_{k-1}) * p(a_{k-1}) \\ 0 & 0 & 0 & c(a_{k-1}, a_{k-2}) * p(a_{k-2}) & -1*p(a_{k-1}) \end{bmatrix} \begin{bmatrix} t(a_1) \\ t(a_2) \\ \vdots \\ t(a_{k-2}) \\ t(a_{k-1}) \end{bmatrix} = \begin{bmatrix} -e_{v0} \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad (4)$$

the total length of overlapped parts of their time slices has length t_0 . Thus, the energy harvested by u_i from u_j in s_1 is $c_{i,j} * p(j) * (t(j) - t_0)$. Contrastively, since that the time slices of u_i and u_j in s_2 are disjoint, the energy harvested by u_i from u_j in s_2 becomes $c_{i,j} * p(j) * t(j)$. Since that $c(i, j) \geq 0$, u_i 's final energy $e_i(s_2, t_E(s_2)) \geq e_i(s_1, t_E(s_1))$. The same analysis applies to u_j and we have $e_j(s_2, t_E(s_2)) \geq e_j(s_1, t_E(s_1))$. With the fact $c_{i,j} + c_{j,i} > 0$ for neighboring nodes u_i and u_j , we know that at least one $e_k(s_2, t_E(s_2)) \geq e_k(s_1, t_E(s_1))$, $k \in \{i, j\}$, strictly holds. Considering the given precondition that there are no energy upper limit violations, all harvested energy will be able to be stored, hence we have Eq.(5).

$$\begin{aligned} E_C(s_2) &= e_i(s_2, t_E(s_2)) + e_j(s_2, t_E(s_2)) \\ &\quad + \sum_{k \in \mathcal{N}(n), k \neq i, j} e_k(s_2, t_E(s_2)) \\ &> e_i(s_1, t_E(s_1)) + e_j(s_1, t_E(s_1)) \\ &\quad + \sum_{k \in \mathcal{N}(n), k \neq i, j} e_k(s_1, t_E(s_1)) \\ &= E_C(s_1). \end{aligned} \quad (5)$$

- **case2: the set of neighboring nodes whose time slices overlap contains three or more nodes.** Without loss of generality, we assume the set contains k nodes $U_s = \{u_{s1}, u_{s2}, \dots, u_{sk}\}$. Following the same way as in case1, we can analyze the energy of each node in U_s harvested from the other nodes in U_s . We can thus obtain that each node's harvested energy in s_2 must be greater than that in s_1 . Again with the fact that there are no energy upper limit violations, we have $E_C(s_2) > E_C(s_1)$.

Combining above cases, the lemma follows. ■

By combining the previous Theorem 1 and Lemma 2, we can obtain the following theorem easily.

Theorem 2: Optimal energy transmission schedules with maximum accumulated final energy (*i.e.*, minimum energy loss) must be disjoint.

Proof: We prove it by contradiction. Assume there is an optimal solution s_1 which is not disjoint. By Theorem 1, we know that s_1 must have no violations. Then by using Lemma 2 on s_1 , we can obtain a better schedule s_2 , which contradicts with the assumption that s_1 is optimal. ■

C. Reformulate and Solve the WPTERD-Egy Problem

Theorem 2 tells us that, to solve the WPTERD-Egy problem, we need only to consider disjoint schedules, which enables us to re-formulate the WPTERD-Egy problem as a more simplified linear programming (LP) problem and thus easy to solve.

Let t_i be the total length of node u_i 's energy transmission time slices (called as time length of u_i for short) in a schedule, and let $t \triangleq \{t(1), t(2), \dots, t(n)\}$ be the list of all nodes' time lengths, then the final energy of node u_i after performing the schedule can be expressed as Eq.(6). Since that we postpone the treatment for not exceeding the energy storage limits when solving the WPTERD-Time problem, we only consider the restriction of the energy limits on the final energy e_F here.

$$e_F(i) = e_B(i) - p(i)t_i + \sum_{j \in \mathcal{N}(n), j \neq i} c(i, j)p(j)t_j, i \in \mathcal{N}(n). \quad (6)$$

The WPTERD-Egy problem for determining t can then be expressed as **P2** in Eq.(7).

$$\begin{aligned} (\mathbf{P2}) \quad & \max_{t = \{t(1), t(2), \dots, t(n)\}} \sum_{i \in \mathcal{N}(n)} e_F(i) \\ & s.t. \quad Eq.(6); \\ & \quad e_F(i) \geq e_E(i), \quad i \in \mathcal{N}(n); \\ & \quad e_F(i) \leq e_U(i), \quad i \in \mathcal{N}(n); \\ & \quad t_i \geq 0, \quad i \in \mathcal{N}(n). \end{aligned} \quad (7)$$

Using the matrix and vector symbols defined in Table I, problem **P2** can be expressed in matrix form as **P3** in Eq.(8).

$$\begin{aligned} (\mathbf{P3}) \quad & \max_t \quad \mathbf{1}^T * \mathbf{e}_F \\ & s.t. \quad \mathbf{e}_B + \mathbf{C} * \mathbf{p} * \mathbf{1}^T * \mathbf{t} = \mathbf{e}_F; \\ & \quad \mathbf{e}_F \succeq \mathbf{e}_E; \\ & \quad \mathbf{e}_F \preceq \mathbf{e}_U; \\ & \quad \mathbf{t} \succeq \mathbf{0}. \end{aligned} \quad (8)$$

Problem **P2** (*i.e.*, **P3**) is a standard linear programming problem, which can be solved efficiently using mature software optimization packages, such as Gurobi, Cplex, Nlopt, and Snopt, Knitro, Conopt, Stoaminlp, Minlp solve.

V. ANALYSES ON THE WPTERD-TIME PROBLEM

Given an energy transmission schedule, we can group the schedule items into item sets $S^i = \{s_1^i, s_2^i, \dots, s_{mi}^i\}$, $i \in \mathcal{N}(n)$. Thus, S^i contains all mi schedule items where node u_i should transmit energy. Thus, the total energy transmission time length of u_i contains mi time slices with length $t_e(s_j^i) - t_b(s_j^i)$, $j \in \mathcal{N}(mi)$.

Once the energy transmission time lengths of the nodes have been determined in the previous section, the remanent work to solve the WPTERD problem is to schedule the nodes' energy transmission time slices along the time line so that the makespan of the schedule is minimum meanwhile assuring the energy limits are not violated during the process. This problem is the WPTERD-Time problem, which is what the second step

will solve. Violating the upper limits leads to energy loss thus destroying the optimality in term of maximum final energy. Violating the lower limits leads to invalid schedule.

To minimize the makespan of a schedule, we should try to make more energy transmission time slices overlap along the time line, but with the prerequisite that the time slices of neighboring nodes should not overlap with each other, otherwise the optimality in term of energy will be destroyed, as shown by Theorem 2.

The WPTERD-Time problem can be stated formally as follow. *Given a set of static nodes U in a given space with energy harvesting coefficient matrix $C=\{c(i,j)\}$, energy storage capacity limit list e_U (vector), energy storage lower limit list e_L , energy transmitting power list p , beginning energy list e_B , expected energy list e_E , the energy transmission time length vector t , the task is to find a time slice schedule s_c for the time length vector t with minimum time span, meanwhile the energy limits are not violated during the whole process. It can be formulated formally as Eq.(9).*

$$\begin{aligned}
 (\text{P4}) \quad & \min_{s_c \in S_C} \max_{s(i) \in s_c} t_e(i) \\
 \text{s.t.} \quad & e_i(s_c, t_E(s_c)) \geq e_E(i), \quad i \in \mathcal{N}(n); \\
 & e_i(s_c, t_E(s_c)) \leq e_U(i), \quad i \in \mathcal{N}(n); \\
 & e_i(s_c, t) \leq e_U(i), \quad i \in \mathcal{N}(n), t \in [0, t_E(s_c)]; \\
 & e_i(s_c, t) \geq e_L(i), \quad i \in \mathcal{N}(n), t \in [0, t_E(s_c)]; \\
 & [t_b(i), t_e(i)] \cap [t_b(j), t_e(j)] = \emptyset, u_s(i) = u_s(j) \\
 & \quad, s_i, s_j \in s_c; \\
 & [t_b(i), t_e(i)] \cap [t_b(j), t_e(j)] = \emptyset, u_s(i) \neq u_s(j) \\
 & \quad, c(u_s(i), u_s(j)) + c(u_s(j), u_s(i)) > 0, s_i, s_j \in s_c; \\
 & \sum_{\substack{s(j)=i, \\ s(j) \in s_c}} (t_e(j) - t_b(j)) = t(i), \quad i \in \mathcal{N}(n); \\
 & 0 \leq t_b(i) < t_e(i), \quad s_i \in s_c;
 \end{aligned} \tag{9}$$

In the WPTERD-Time problem, besides the restrictions of the energy limits, the main restrictions are that neighboring nodes' time slices should not overlap. The neighboring information of the WPTERD-Time problem can be more conveniently expressed as a graph $G(V, E)$ defined as Eq.(10). This graph is usually called *conflict graph* in the literature of task scheduling.

$$\begin{cases} V(G) = \{ u_i & | & i \in \mathcal{N}(n) \}, \\ E(G) = \{ e(i, j) & | & c(i, j) + c(j, i) > 0, i, j \in \mathcal{N}(n) \}. \end{cases} \tag{10}$$

Besides the restrictions of the energy limits, the core work of the WPTERD-Time problem is an energy transmission task scheduling (ETTS) problem stated as follow: *Given a set of n energy transmission tasks with time lengths $t=[t_1, t_2, \dots, t_n]$ and the corresponding conflict graph $G(V, E)$, to find an energy transmission task schedule with minimum makespan. We can solve the WPTERD-Time problem basing on a solution to the ETTS problem. However, the ETTS problem is hard to solve, as shown in the following Theorem 3, which is proved by inducing from the well-known NP-hard graph coloring (GC) problem.*

Theorem 3: The ETTS problem is NP-hard.

Proof: We prove it by providing a polynomial reduction from the NP-hard graph coloring (GC) problem to the ETTS

problem. The GC problem is to find a coloring for a given graph $G(V, E)$ with minimum number of colors. A coloring of G using k colors is a function $c: V \rightarrow \mathcal{N}(k)$ such that adjacent vertices in G are assigned different colors.

For the GC problem with graph $G(V, E)$, we create an ETTS problem with $|V(G)|$ tasks all with unit time length, and meanwhile it utilizes $G(V, E)$ as its conflict graph. It is obvious that the creation of the ETTS problem instance from the GC problem instance is polynomial. Furthermore, it is easy to notice that there is a one-to-one map between the coloring solutions of the GC problem and the task schedules of the ETTS problem. To be specific, we divided the time line for the ETTS problem into time slots with unit length, then let the nodes whose corresponding vertices are colored with 1 in the coloring solution of the GC problem instance transmit energy in the 1st time slot, and then those nodes corresponding to color 2 should transmit in the 2nd slot, and so on. The makespan of the ETTS problem is just the number of the colors in the GC problem. As a conclusion, there is a polynomial reduction from the NP-hard GC problem to our ETTS problem. The theorem follows. ■

Theorem 4: The WPTERD-Time problem is NP-hard.

Proof: We prove it by providing a polynomial reduction from the ETTS problem to the WPTERD-Time problem. For the ETTS problem with conflict graph $G(V, E)$ and task time length list t , we can build an instance of WPTERD-Time problem with its parameters constructed as follows. We can use any matrix as C on condition that it satisfies: (1) diagonal elements take value -1; (2) all elements corresponding to edges in G take values from (0,1); (3) all other elements take value 0; (4) $c(i, j) + c(j, i) > 0$ for all edges $(i, j) \in E(G)$. $e_L=0$, $e_U=\inf$, $p=1$, $e_B=\max(t)+1$, and $e_E=e_B+C*t$. This can obviously be done in polynomial time.

Then it is easy to check that any schedule to the instance of the ETTS problem is a valid energy transmission schedule to the constructed instance of the WPTERD-time problem, and vice visa. In other words, the solutions to the ETTS problem instance and those to the WPTERD-Time problem have a one-to-one map. Hence, the theorem follows. ■

VI. SOLVE THE WPTERD-TIME PROBLEM

Theorem 3 and Theorem 4 imply that it seems no polynomial algorithms to solve the two problems optimally. Hence, we propose an algorithm to solve the WPTERD-Time problem in two steps. In the first step, it solve the ETTS problem to obtain the collection of energy-transmission concurrent set, which means that the nodes in the set should transmit energy concurrently for a certain time length associated with the set. Step 1 just returns a collection of energy-transmission concurrent sets, whereas the sequence in which the energy transmission operations of the nodes in the sets are not determined. Hence in the second step, it determines the final schedule considering energy limits based on the energy-transmission concurrent set collection.

A. Step1: The LNSWL-SS algorithm for the ETTS problem

Inspired by the smallest-degree-last algorithm for approximately solving the GC problem, we propose our algorithm for

the ETTS problem. Our algorithms first determines a sequence with nodes having least weight local neighbor set sequenced at last. Then schedule the tasks greedily following this sequence. When scheduling for each task, the task is scheduled to run in any time slice not occupied by any of its conflicting neighbors. We name the algorithm as Least Neighbor-Set-Weight Last Sequential Scheduling(LNSWL-SS) algorithm.

The pseudo code of LNSWL-SS is shown in Alg. 1. The algorithm solve the ETTS problem in three stages. The while-loop between lines 1-1 implement the first stage, where it generates the sequence in which the tasks will be scheduled sequentially, meanwhile obtain a property value of graph G , defined as $\varpi(G) \triangleq \max_{H \subseteq G} (\min_{v \in H} w(N_{H,y}(v)))$, which denotes the largest ϖ such that G contains a subgraph H in which each node's neighbor-set-weight is at least ϖ . Then in the second stage, the for-loop between code lines 1-1 greedily schedules the tasks one by one in this sequence by assigning all unused time slices not occupied by already determined schedule items of the current neighbor being scheduled. In last stage, code lines 1-1 generate the list of concurrent tasks in each time slot according to S_{si} obtained in the previous stage.

Algorithm 1 Least Neighbor-Set-Weight Last Sequential Scheduling(LNSWL-SS) algorithm

Require: $G(V, E, W)$: weighted conflict graph of the problem;

Ensure: $v_{List}[1:n]$: the node list representing the scheduling sequence;

S_{si} : the set of schedule items;

S_{cts} : the collection of energy-transmission concurrent sets;

$\varpi(G)$: $\varpi(G) \triangleq \max_{H \subseteq G} (\min_{v \in H} w_N(H, v))$;

1: Initialize $G' = G(V, E)$, $\varpi(G) = 0$, $v_{List} = []$;

2: **while** $G' \neq \emptyset$ **do**

3: $\varpi(G) = \max(\varpi(G), \min_{v_j \in V(G')} w_N(G', v_j))$;

4: $v_i = \arg \min_{v_j \in V(G')} w_N(G', v_j)$;

5: $v_{List} = [v_i, v_{List}]$;

6: $V' = V(G') - v_i$; $E' = E(G') - \{e(i, k) | e(i, k) \in V(G')\}$;

7: $G' = G(V', E')$;

8: **end while**

9: **for** $i = 1:n$ **do**

10: Assign all time slices unused by any schedule items of the nodes in $N(G', v_i)$, i.e., the neighboring nodes of v_i in G' , and insert the corresponding schedule items into S_{si} ;

11: **end for**

12: Sort the beginning and ending times of all schedule items into a list $T_s(s_c) = [t_1, t_2, \dots, t_L]$ in ascending order (we assume the list has length L), we thus obtain $L-1$ time slots with slot i occupies time $(t_i, t_{i+1}]$.

13: **for** $1 = 1:L-1$ **do**

14: obtain the set $U_T(i)$ of concurrent tasks in time slot i ;

15: $S_{cts}(i).CTs = U_T(i); S_{cts}(i).TimeLen = t_{i+1} - t_i$;

16: **end for**

17: **return** $S_{si}, S_{cts}, \varpi(G)$;

B. Step2: Energy Transmission Schedule Considering Energy Limits

This step determines a time-set schedule sequence of energy transmission time slices, where each sequence item determines the set of nodes that should transmit energy together with the time length of the time slice. This is determined by our algorithm named as energy-transmission concurrent set scheduling (ETCS-S) algorithm, which makes use of the collection of energy-transmission concurrent sets determined by the LNSWL-SS algorithm in step 1. The pseudo code of ETCS-S is shown in Alg. 2.

The ETCS-S algorithm firstly inserts all sets in the collection of energy-transmission concurrent sets into a queue. These sets are called as candidate schedule items. The algorithm determines the available time slice lengths for the candidate schedule items in the queue in turn (code lines 9-19 in Algorithm 2). The slice length t_3 is mainly determined whichever is earlier: (1) the earliest time that one node's remaining time becomes 0 (code line 2 in Algorithm 2); (2) the earliest time that some node in T_A reaches its lower energy limit e_L (code line 2 in Algorithm 2); (3) the earliest time that some node reaches its upper energy limit, which is determined using the bisection search method when necessary (code line 2 in Algorithm 2). The other code lines update the candidate schedule items correspondingly and generating new candidate schedule items when necessary.

There are cases that neighboring nodes are both with full energy $e_B = e_U$ before the re-distribution. In this case, the binary search will fails to return a positive value. In fact, there is no way to keep the upper limits un-violated while keeping the energy optimality of the schedule. One such case is shown in Fig.3. The parameters are as follows: energy upper limit $e_U = [10, 10, 10]$, energy at the beginning $e_B = [10, 10, 1]$, energy expectation $e_E = [6, 6, 2]$, and energy transmission power $p = [10, 10, 1]$. It is easy to check that the energy transmission time length solution to the corresponding WPTERD-Egy problem will be $t = [5, 5, 0]$. Whichever u_1 and u_2 performs the energy transmission first, energy upper limit violation will happen at the other node. If we let them transmit energy simultaneously, optimality in energy will be damaged. To solve this dilemma, we compromise the energy optimality by allowing a short time period ϵ for energy loss/overflow (code line 2 in Algorithm 2). After that period, the two nodes can perform energy transmissions alternatively. One node keeps transmitting until the other reaches its energy upper limit, or the energy transmission time is used up. The energy changing processes of the nodes along with time using such an schedule are shown in Fig 4. Since that energy harvesting coefficient is quite small, the time length that continuous energy transmission time periods will increase rapidly. With small enough ϵ , the amount of energy loss may be trivial. The energy loss approaches 0 as $\epsilon \rightarrow 0$.

C. Performance Ratios of the LNSWL-SS Algorithm

The rough superiority of the solutions returned by an approximate algorithm is usually implied by its performance ratio. Performance ratio of an algorithm is a constant $\rho \geq 1$ such that, for any instance I of the maximization(minimization)

Fig. 3. An example without practical schedules assuring energy optimality of the WPTERD-Egy problem's solution.

problem, the value of any solution returned by the algorithm is at least $1/\rho$ (at most ρ times of) of the optimal value. A polynomial time approximation scheme (PTAS) for a problem is a polynomial time approximation algorithm which guarantees performance ratio of $1+\epsilon$ for some $\epsilon > 0$.

For general graphs, the graph coloring problem is NP-hard even for any fixed number of colors $k \geq 3$ [18]. Furthermore,

Fig. 4. The energy changing processes of the nodes along with time of a schedule for the example in Fig.3.

it is hard to approximate, i.e., the problem of approximating the chromatic number with any constant ratio is also NP-hard [19]. Fortunately, for the ETTS problems embedded in the WPTERD-Time problem, the conflict graphs are intersection graphs of the nodes' energy signal coverage disks, we find that our LNSWL-SS Algorithm has constant approximations.

Lemma 3: The LNSWL-SS Algorithm can definitely find a solution to the ETTS problem with makespan not greater than $\varpi(G)$, i.e., all time slices fall in time interval $[0, \varpi(G)]$.

Proof: We will prove it by induction. The LNSWL-SS algorithm determines the time slices of the nodes in the sequence of $v_{List}[1:n]$. For the first node $v_{List}(1)$, it is obvious that its energy transmission operation can definitely be scheduled in time interval $[0, \varpi(G)]$. Now assume that the time slices for the nodes in $v_{List}[1:i]$ are in $[0, \varpi(G)]$. According to the definition of $\varpi(G)$ and the construction of the list $v_{List}[1:n]$, we must have $w(N(v_{List}(i+1))) \leq \varpi(G)$, otherwise we will have $\varpi(G) \geq w(N(v_{List}(i+1)))$ according to the way $\varpi(G)$ is updated by code line 1. Hence, we can surely schedule node $v_{List}(i+1)$'s energy transmission operations in between the time slices occupied by its neighbors meanwhile kept in interval $[0, \varpi(G)]$. The lemma follows. ■

Lemma 4: For WSNs in 2D space, if the nodes' energy coverage disks have equal radii, then the LNSWL-SS Algorithm has an approximation ratio of 3.

Proof: Our proof mimics the proof of the theorem in [20]. First, the makespan m_{OPT} of any optimal schedule must not be smaller than the weight of the maximum clique $w_{c,G}$, we have Eq.(11).

$$m_{OPT} \geq w_{c,G} \quad (11)$$

We let H be a subgraph of G such that every node in H has neighbor-set-weight at least $\varpi(G)$, and let $v^* \in H$ be the node having smallest Y . Using the definition of $\varpi(G)$ and Lemma 3, we have Eq.(12).

$$w_{N,y}(v^*, H) \geq \varpi(G) \geq m_{LNSWL} \quad (12)$$

Since that v^* has the smallest Y coordinate in H , all nodes in H must be in the top half plane above the horizontal line

through node v^* . We divide the right half disk with radius r into three equal sections as shown in Fig.5, where nodes represented by blue circles are the nodes in $N(v^*, H) = H \cap N(v^*)$. Nodes on the division lines can be assumed to be in either of the two adjacent sections deterministically.

Fig. 5. Divide the top half disk into 3 sections.

Since that all the nodes have energy signal radius r , it is obvious that the nodes in each section form a clique. Assume the maximum weight clique of the graph G has weight $w_{c,G}$, then we have Eq.(13).

$$\begin{aligned} w_{N_y}(v^*, H) &= w(S_1 \cap H + S_2 \cap H + S_3 \cap H - 2 * w(v^*)) \\ &\leq w(S_1 \cap H + S_2 \cap H + S_3 \cap H) \leq 3 \\ &\leq 3 * w_{c,G} \end{aligned} \quad (13)$$

Combining the equations from Eq.(11) to Eq.(13), we obtain $m_{\text{LNSWL}} \leq 3 * m_{\text{OPT}}$. The lemma follows. ■

Lemma 5: For WSNs in 3D space, if the nodes' energy coverage spheres have equal radii, then the LNSWL-SS Algorithm has an approximation ratio of 12.

Proof: The proof process is identical to that used in the previous lemma, but with some adaptations to the 3D space. The differences lie in the following aspects. (1) v^* represents the node with smallest Z coordinate value in H ; (2) divide the top half sphere into 12 sections as shown in Fig.6 (firstly use the planes $X=0$ and $Y=0$ to split the half sphere into 4 equal sections, then divide each section into 3 sections using three planes, each of which contains the line through point $(0,0,0)$ and the center point of the section's spherical face meanwhile perpendicular to the partition planes).

Fig. 6. Divide the top half sphere into 12 sections.

It is easy to notice that any two points in one section has distance not greater than coverage radius r . For

example, the distances between the points A, D, E, F in the same section in Fig.6 can be obtained easily as $l_{DA} = r * \sqrt{(1 - 1/\sqrt{3})^2 + 2 * (1/\sqrt{3})^2} \approx 0.9194r < r$, $l_{DE} = l_{DF} = r * \sqrt{2(1/\sqrt{2} - 1/\sqrt{3})^2 + (1/\sqrt{3})^2} \approx 0.6058r < r$, $l_{EF} = r * \sqrt{2 * (1/\sqrt{2})^2} = r$. Thus, all nodes in each section must form a clique.

Applying the analysis process to the 3D case with above adaptations, we obtain $m_{\text{LNSWL}} \leq 12 * m_{\text{OPT}}$. The lemma follows. ■

For the general case of the nodes' energy transmission signals having different coverage radius, we have the following lemma about performance ratio of LNSWL-SS.

Lemma 6: For WSNs in 2D (3D) space, if the radius of the nodes' energy coverage disks (spheres) do not equal, then the LNSWL-SS Algorithm has an approximation ratio of 6 (24).

Proof: These can be proved by applying an analysis method similar to that used in proving the previous lemmas, but with some adaptations to the non-equal radii condition. To be specific, assume H is a subgraph of G such that every node in H has neighbor-set-weight at least $\varpi(G)$, we select $v^* \in H$ be the node having smallest radius r_1 . Thus, all other nodes in H may lie around the node v^* , instead of lie in a half space of v^* . Hence, for assuring that all nodes in a section form a clique, for the 2D case, we have to divide the disk centered at v^* with radius r_1 into 6 equal sections as shown in Fig.7.

Fig. 7. Divide the disk centered at v_* with radius r_1 in 2D space into 6 sections.

For the 3D case, we have to divide the sphere centered at v^* with radius r_1 into 24 equal sections as shown in Fig.8.

Further analyses will correspondingly result to performance ratio of 6 and 24, respectively. The lemma follows. ■

VII. SOLVE THE WPTERD PROBLEM

Based on previous analyses results and the preliminary algorithms proposed, we can thus solve the WPTERD problem by decoupling the problem into WPTERD-Egy problem and WPTERD-Time problem. The two problems focus exclusively on the optimization in energy and time, respectively. Based

Fig. 8. Divide the sphere centered at v_* with radius r_1 in 3D space into 24 sections.

on this approach, we propose our algorithm named Energy Time Decoupling (ETDeCouple) algorithm. ETDeCouple first solve the **P3** problem using mature LP optimization softwares to obtain \mathbf{t} . Then, it obtains S_{cts} by using the LNSWL-S algorithm to solve the corresponding ETTS problem, and at last generates a schedule TS_{ss} from S_{cts} by using the ETCS-S algorithm. The pseudo code of ETDeCouple is shown in Alg.3.

Algorithm 3 The ETDeCouple algorithm

Require: e_B, e_U, e_L, e_E, C, p ;

Ensure: TS_{ss} : the time-set schedule sequence;

- 1: $[\mathbf{t}] = \text{solveP3}(e_B, e_O, e_U, C, p)$; %using to solve and obtain \mathbf{t} ;
 - 2: create $G(V, E, W)$ for the corresponding ETTS problem using \mathbf{t} ;
 - 3: $[S_{cts}] = \text{LNSWL-SS}(G(V, E, W))$;
 - 4: $[TS_{ss}] = \text{ETCS-S}(S_{cts}, e_B, e_U, e_L, e_E, C, p)$;
 - 5: **return** TS_{ss} ;
-

By using the ETDeCouple algorithm to carefully schedule the energy transmissions of the nodes in WSNs, we are able redistribute energy in the network, which implicitly realizes the multi-hop energy flow efficiently but easily. Meanwhile, the broadcasting nature of radio signals is well exploited to achieve the most energy efficient way to conduct the energy redistribution.

VIII. PERFORMANCE EVALUATION

A. Performance Metrics

We conduct numerical simulations using Matlab 2015a on a computer with Win10-bit64, 2.21GHz i7-CPU, and 8GB Memory. Three performance metrics are used: *Energy Loss Ratio*, *Schedule Makespan*, and *Switch Number*. The energy loss ratio metric is calculated as $\frac{\sum_{i \in \mathcal{N}(n)} (e_B(i) - e_F(i))}{\sum_{i \in \mathcal{N}(n), e_E(i) > e_B(i)} (e_E(i) - e_B(i))}$, which implies the side 'cost' for redistribute energy in the

network using the algorithm. The makespan metric represents the the time span of the energy transmissions of a schedule, which reveals the time efficiency of a schedule. The switch number metric represents the number of energy transmissions slices of the nodes in the schedule, which is obtained by counting the starts of energy transmissions. This metric implies the number of node status changes in a schedule. We obviously prefer smaller energy loss, smaller schedule makespan, and smaller switch number.

B. Simulation Setup

We test our GERDS algorithm with two node selection policies: (1) select the node with maximum t , (2) select the node whose energy is most close to e_U (i.e., to select the node with maximum energy if all nodes have the same e_U). We denote them as GERDS-MaxT and GERDS-MaxEg, respectively. For comparison purpose, we implement another algorithm denoted as AlgNoParallel, where the nodes transmit energy one by one without parallel, even for not-neighboring nodes. In AlgNoParallel, the time for each continuous energy transmission slice is determined in a way similar to that in GERDS. Additionally, it is obvious that the maximum clique of the weighted graph $G(V, E, W)$ of the WPTERD-Time problem is a lower bound for the makespan of an optimal schedule. We use a greedy-based algorithm denoted as LBClique to approximately solve the maximum weight clique problem and use it as a baseline for performance evaluation. Thus, totally four algorithms are tested in our simulations: GERDS-MaxT, GERDS-MaxEg, AlgNoParallel, LBClique.

Main parameters and the default values in our simulations include *number of nodes* $n=100$, *side length* $L=10$ of the square network region, *energy transmission power* $p=1$, *ratio of energy-needing nodes* $\eta=0.3$, and *the amount of energy required by these energy-needing nodes* $e_h=5$, $e_U=100$, $e_L=20$. The energy harvesting coefficients are set as $\alpha=0.3$, $\beta=1$, $\gamma=2$, and $D=4$. A set of particular values for these parameters is called a **simulation configuration**. For each simulation configuration, 100 problem instances are generated and treated using the tested algorithms in turn. The WPTERD-Egy problem of randomly generated WSNs may have no LP solutions at all, in such cases new problem instances are generated repeatedly until a valid problem instance is obtained. In each problem instance, n nodes are randomly placed in the square region $L \times L$ (Although our analysis applies to 3D space, we restrict our simulations for 2D case without sacrificing the effectiveness of the simulation results). $e_B(i)$, $i \in \mathcal{N}(n)$, are randomly selected in $[e_L, e_U)$ following the uniform distribution. Randomly select $\lceil n \cdot \eta \rceil$ energy-needing nodes and set $e_E(i)$ of each node u_i in this set to be $e_E(i) + e_h$. All the others nodes' energy expectations are set to e_L . Results of the performance metrics are collected and averaged to obtain the final results for the simulation configurations. The 95% confidence intervals of the performance metrics are also calculated.

C. Simulation Results

In our simulation experiments, the effects of a parameter on the algorithms' performance are obtained by performing a

simulation set consisting of similar simulation configurations. The simulation configurations in such simulation set only difference in the value of this parameter, whereas all the other parameters take their default values. We conduct simulation experiments for inspecting the effects of the main parameters. All simulation results verify the efficiency of our algorithms. Here we only provide the simulation results for parameter n for space limitation.

In the simulation experiment for n , we let n take values in range from 10 to 100 with step size 10. The results are shown in Fig.9. The energy loss ratio switch number metric is not applicable to LBClique. Since that the other three algorithms make schedules based the shared solution t of **P3**, there are no distinctive differences in the energy loss ratio metric, as shown in Fig.9(a). As n increases, the energy loss ratio decreases quickly. This is reasonable since that, with higher node density, the energy harvesting coefficients will be much larger, and more nodes can harvest energy from the single energy transmission. These two factors both lead to less energy loss when transmitting energy to others. The results in Fig.9(b) show that, GERDS-MaxT and GERDS-MaxEgy obtain similar makespans, which are both no more than 120% of LBClique. These results imply that GERDS-MaxT and GERDS-MaxEgy are nearly optimal. Compared with AlgNoParallel, GERDS-MaxT and GERDS-MaxEgy reduces the makespan metric by more than 60% when $n=100$, and the it will become more effective in this metric as n increases. These results imply that the GERDS based algorithms can exploit the parallel energy transmitting opportunities well. This is obtained at the cost of a little more operation status switches, as shown in Fig.9(c). GERDS-MaxEgy outperforms GERDS-MaxT in this metric. Compared with AlgNoParallel, when $n=100$, GERDS-MaxEgy incurs only about 5% more switches, whereas it is about 20% for GERDS-MaxT.

IX. CONCLUSION

In this paper, we propose a two-step approach to solve the WPTERD problem by solving two embedded sub-problems WPTERD-Egy and WPTERD-Time in turn. In the first step, by formulating the WPTERD-Egy problem based on interesting property of the problem in a linear programming (LP) form, we obtain the optimal energy transmitting time lengths of the nodes leading to minimum energy loss. With the results in the first step, the remanent work of the WPTERD problem becomes the WPTERD-Time problem, which is to find a minimum makespan schedule not violating the nodes' energy limits. We prove that the WPTERD-Time problem is NP-hard, and then we propose a greedy-based heuristic algorithm named GERDS to solve it. Numerical simulations illustrate the effectiveness and efficiency of GERDS, which return schedules with minimum energy loss and approximately minimum makespan. By exploiting parallel opportunities of energy transmissions, GERDS reduces makespan by more than 60% when compared with a schedule without exploiting the parallel energy transmission opportunities.
